Abstract

The South American tomato pinworm, *Tuta absoluta*, is considered worldwide as one of the most important tomato pests. Insecticide resistance reported on the moth and the awareness about the negative impact of agrochemicals on the environment and human health, has raised the demand for new control tools. Among these, RNA interference (RNAi) can represent a valid tool to be included into new control strategies against this pest. Here we report the results of trials aimed at evaluating the effects of dsRNAs targeting Acetylcholinesterase (AChE), Nicotinic Acetylcholine alpha 6 (nAChRs), Ryanodine (RyR) and receptors by injection and root delivery. In the injection procedure 2 and 5 µg of dsRNA were able to reduce the gene expression in a range of 62.7-75.4%, inducing a maximum mortality rate of 92.59%. The dsRNAs administered at 5 µg by root adsorption revealed the potential of this delivery system to affect the gene expression (47-69% reduction of) and the mortality (ranging from 67.1 to 80.5%) of treated specimens. The delivered dsRNAs (both injections and root administered) affected the weight of developed *T. absoluta* both prepupae and pupae. The selected AChE, nAChRs and RyRs genes can be suitable targets for *T. absoluta* control by means of *in planta* delivery dsRNAs.

Keywords: RNA interference, Hydroponic, Ryanodine Receptor, Acetylcholinesterase, Nicotinic Acetylcholine Receptor, Tomato

Key message

- RNAi is a promising tool for the control of insect pest.
- We tested three dsRNAs against *T. absoluta* preimaginal stages.

- 61 • The dsRNAs had effect on moth mortality both by injection and root delivery.
- 62 • The dsRNA root adsorption represent a potential route to develop control strategy to be
- 63 applied in real field conditions.

64

65

67 Introduction

68 Agricultural pests cause annual crop losses worth billions of US dollars (Bingsohn et al. 2017).
69 In many cases, insecticide applications are one of the major pest control approaches. Despite
70 its negative effects, chemical control is normally considered quicker and more effective
71 compared to other pest control methods. (Geiger et al. 2010; Pimentel et al. 2005). The wide
72 spread of insecticides has led to the rapid development of insecticide resistance and also to
73 a negative effects on non-target organisms, persistence and biomagnifications in the
74 environment, which cause environmental as well as health related problems (Desneux et al.
75 2007; Weston, et al. 2015; Cimino et al. 2017)

76 The South American Tomato Pinworm, *Tuta absoluta* (Meyrick) (Lepidoptera: Gelechiidae) is
77 a small oligophagous Lepidoptera that feeds of many solanaceous species and has a
78 particular preference for tomato (*Solanum lycopersicum* L.) (Desneux et al. 2010; Campos et al.
79 2017; Biondi et al. 2018), causing up to 100 % damage if not controlled (Desneux et al. 2011). It
80 can develop on other cultivated Solanaceae such as potato, eggplant, sweet pepino (*Solanum*
81 *muricatum* L.) and tobacco (*Nicotiana tabacum* L.), as well as on wild plant species [Jimson
82 weed (*Datura stramonium* L.), black nightshade (*Solanum nigrum* L.) and deadly nightshade
83 (*Atropa belladonna* L.)] (Tropea Garzia et al. 2012; Cherif et al. 2018).

84 This pest was first reported in Perù at the beginning of the 20th century and it is currently
85 recorded in more than 80 countries around the world and affecting nearly 60% of all cultivated
86 tomatoes (Biondi et al. 2018). After its first report in Spain in 2006, it spread quickly in Europe

and North Africa and has subsequently invaded the Middle East, Central and South Asia (Desneux et al. 2011; Sankarganesh et al. 2017; Sylla et al. 2017; Mansour et al. 2018) threatening China, i.e., the major tomato producer country (Xian et al. 2017; Han et al. 2018).

In many tomato cropping systems, chemical applications are necessary and often resulted in overuse of these chemicals. This caused the disruption of integrated pest control strategies where natural enemies are largely employed (Biondi et al. 2012; 2013; Zappalà et al. 2013). Moreover, because of the high reproductive potential (up to 300 eggs per female) and short generation cycle (10 to 12 generations per year) (Tropea Garzia et al. 2012; Biondi et al. 2018), this moth can rapidly develop resistant populations to insecticides belonging to different chemical classes (Roditakis et al. 2017). The insecticide resistant populations of the pest were detected in the early 2000s in Chile, Brazil and Argentina and include resistance to organophosphates (OPs), pyrethroids, abamectin, cartap, spinosad and diamides (Siqueira et al. 2000; Lietti et al. 2005; Haddi et al. 2012; Roditakis et al. 2015, 2017; Zibaee et al. 2018).

Therefore, the development of novel and effective alternative control methods are urgently needed (Cocco et al. 2013; Sohrabi et al. 2016; Campolo et al. 2017).

Recently, biotechnology has provided additional techniques to decrease the damage caused by insect pests while at the same time it has given solutions for the limitations of traditional and hazardous chemical methods (Christou et al. 2006). Therefore, new strategies for pest control are required imperatively and one promising approach is the use of RNA interference (Bingsohn et al. 2017).

RNA interference (RNAi) is a biological mechanism which leads to post transcriptional gene silencing directed by the presence of double-stranded RNA (dsRNA) molecules to prevent the

expression of specific genes occurs widely among plants, animals and microorganisms resulting in the degradation of the targeted mRNA (Kim et al. 2015). Since the discovery that providing double-stranded RNA (dsRNA) to a wide variety of organisms, including insects, can cause RNAi, this technique has become a common tool for functional genomic studies, especially in non-model systems. It has been exploited successfully as a powerful reverse genetic tool to study the function of genes and for biological control of various agricultural insect pests and pathogens (Price and Gatehouse 2008; Zotti and Smagghe 2015; Mamta and Rajam 2017). Because biological compartments are regulated by numerous proteins and enzymes, the identification of the most promising gene targets is one of the major challenges to exploit RNAi in pest control strategies (Laudani et al. 2017).

In this context, the aim of this research was to evaluate the effects on *T. absoluta* of three dsRNA delivered by injection and root adsorption in tomato plants. The target genes for this study were the Ryanodine Receptors (>KX519762.1)(RyRs), Acetylcholinesterase subunit 1 (>KU985167.1)(AChE) and Nicotinic Acetylcholine Receptor alpha 6 (>KP771859.1)(nAChRs). Owing to the involvement of these genes in nerve transmission and other metabolic processes, they have been effective targets for controlling insect pests of crops by applying chemical insecticides.

Materials and Methods

Insects

The population of *T. absoluta* used in the study originated from field collected specimens from tomato fields of Hashtgerd Region, Karaj, Albarz Province, Iran. The moth was reared on tomato plants or leaves at the Department of Agriculture of Mediterranean University of Reggio Calabria, Italy, under laboratory conditions (25 ± 2 °C; $60 \pm 10\%$ relative humidity; 14 h photoperiod) for several generations according to Zappalà et al. (2013). Cherry-type pesticide-free tomato plants (cv Shiren) were used for rearing and experiments.

RNA extraction and cDNA synthesis

Total RNA was extracted and purified from 100 mg of the third instar larvae of *T. absoluta* using TRIzol® (Invitrogen; Carlsbad, CA, USA) and Pure Link® RNA Mini Kit (Cat. No. 12183025, Life Technology). The quality and quantity of the extracted RNA was determined by using a Nanodrop 2000 spectrophotometer (Thermo Fisher Scientific Inc., USA). cDNA synthesis are performed in 20µl reactions comprised of components of the ImProm-II™ Reverse Transcription Kit (#A3800, Promega) by using about 1µg experimental RNA, according to the manufacturer's instruction. The synthesized cDNA was used as a template to amplify a portion of the coding sequence of AChE, nAChR and RYAR genes selected from the NCBI database, using the primers reported in Table 1. The synthesized cDNA was then stored at -20 °C.

dsRNA synthesis

Target genes, selected from the NCBI database and primer pairs were designed using Primer-BLAST software® (Table S1). For dsRNA Synthesis, a T7 promoter sequence (5'-TAATACGACTCACTATAGGG-3') was ligated to the amplicons, including this sequence at the 5'

ends of each primer. Amplifications were performed using a Mastercycler Ep Gradient S thermocycler (Eppendorf, Germany) with the following conditions: 5 cycles at 94°C for 2 min, then 94°C for 30 s, 55°C for 30 s and 72°C for 45 s, followed by 35 cycles at 94°C for 30 s, 60°C for 30 s and 72°C for 45 s, with a final extension step of 10 min at 72°C. A non-template control in which target cDNA was replaced by nuclease-free water was also included in all PCR reactions. PCR products were analyzed by Nanodrop and gel electrophoresis in TBE buffer (1X) using 1% agarose gel. The dsRNA fragments were generated using MEGAscript®RNAi Kit (Ambion) according to manufacturer's instructions. The final concentration and quality of dsRNA products were measured by Nanodrop. The quality and integrity of dsRNA was also checked by electrophoresis on 1% agarose gel.

The negative control groups were injected with the same concentration of a 495 bp-long dsRNA molecule targeting the green fluorescent protein being absent in *T. absoluta* to assess the effect of injecting and feeding the target-less dsRNA. Molecular biology grade water was administered as further negative control. As internal controls, ribosomal protein 18S (Rp18) were used.

Administration of dsRNA by injection and through root delivery

Newly molted third instar larvae were used for assays because they are the easier instar to manipulate in this kind experiment. In the injection delivery procedure, the dsRNA of each gene was injected with 2 different concentrations (2 and 5 µg per each larva) on the dorsal side of the first or second abdominal segment of each larva (Tomoyasu and Denell 2004) using Eppendorf Microinjector®InjectMan NII. Injected larvae were transferred on tomato untreated

173 leaflets and kept in a climatic chamber (Cavallo 1400 CFU, Milano, Italy) under the same
174 climatic conditions adopted for the rearing procedures.

175 Control larvae were injected with dsGFP (Green Fluorescent Protein) and nuclease-free water
176 as negative controls and kept in the same condition as the other treatments. Dead larvae within
177 the first 48 hours after the injection were removed and excluded from the experiments. The
178 injection was carried out for all three genes separately, employing, for each treatment, groups
179 of 5 individuals. The experiment was replicated three times.

180 In the administration of dsRNAs through roots, the petiole of detached two weeks old fully
181 expanded tomato leaves (cherry-type, cv Shiren) was immersed for 6 days in oxygenated sterile
182 water. This ensured a complete rooting of the leaves. The larvae used in the experiments were
183 left starving for two hours prior starting the tests. Then the roots were immersed in 200 μ L of
184 water containing 5 μ g of dsRNA (the most effective dose in the injection procedure, see results
185 below) from each target gene. The rooted leaves were left until the dsRNA solution was
186 completely absorbed, and this took around 3 hours. Control treatments were treated with
187 nuclease-free water and dsGFP solution adopting the same procedure above described.

188 Immediately after the uptake, five third instar larvae were gently placed onto the leaves for
189 feeding. The trial was replicated three times.

190 For both dsRNAs delivery routes, the effects of RNAi on the larvae were evaluated, after 72h, by
191 quantitative amplification of reversed transcripts (RT-qPCR) of each target gene compared to
192 the controls.

193

194 **Effects of dsRNA administration on mortality, biometric and morphometric traits of T.**
195 **absoluta.**

196 To evaluate the effects on mortality, biometric and morphometric traits due to the dsRNA on T.
197 *absoluta* two separate experiments were carried out.

198 In the first experiment, 2 or 5 µg dsRNAs of the three targeted genes, were injected in each of
199 fifteen newly molted 3rd instar larvae, after the injection of dsRNAs each larvae was
200 individually placed in a small petri dish and fed with untreated leaflets.

201 In the second experiment, the delivery of dsRNAs was carried out by root adsorption. The roots
202 were immersed in 200 µl of water containing either 5 µg of dsRNA of each target gene and left
203 to absorb all the dsRNA solution for 3 hours. Then a newly molted third instar larva was gently
204 placed onto each rooted leaf for feeding.

205 The rate of mortality and any changes in larval stages, weight and phenotypic changes were
206 recorded every 24 hours, and observations were carried out until all the adults emerged.

207 Controls with dsRNA from the GFP gene sequence and nuclease-free water were run in parallel
208 as well. Each trial was replicated three times.

209 **Cloning**

210 The template cDNA was denatured at 95°C for 5 min followed by 25 cycles at 95 °C for 30
211 seconds and annealing temperature at 55 °C for another 30 seconds followed by 30 seconds
212 extension time at 72 °C, the PCR reaction was ended at 72 °C for 7min. The PCR products were
213 subsequently purified using MinElute Extraction Kit (QIAGEN® Venlo, Netherlands) and cloned
214 using Strata cloning® kit (Agilent Technologies® Santa Clara, USA). Three insertion-positive *E.*

coli colonies for each amplified gene were selected, the fragment was cut from the vector using EcoRI enzyme (Thermo Fisher Scientific, USA), and it was sequenced by MacroGen Laboratories in order to check for the amplification of the correct target. dsRNAs for each target was synthesized starting from 1000 ng/μl cDNA, and through specific primers using the MEGAscript® RNAi Kit (Thermo Fisher Scientific®, USA) according to the manufacturer's instructions. The quality and integrity of dsRNA was also checked by electrophoresis on 1% agarose gel. Products were also quantified using a Nanodrop 2000 (Thermo Fisher Scientific®, USA), obtaining an average concentration ranging between 700-1000 ng/μl.

Gene expression analysis with quantitative reverse transcription PCR (RT-qPCR)

The total RNA was extracted and processed into cDNA as described above. RT-qPCR was carried out using primers listed in Table 1, designed to detect a segment of each gene selected to be external to the segment targeted by the dsRNA. The ribosomal protein Rp18 was used as an internal reference gene. The levels of mRNA were measured by StepOnePlus™ Real-Time PCR System (Life Technologies®) using the GoTaq- qPCR MasterMix (Promega, USA, #A6001) according to the manufacturer's instructions. Reaction were performed using the following conditions: 95°C for 3 min, 50 cycles of 95 °C for 3 seconds and 60 °C for 30 seconds, and a final dissociation stage. The relative expression of the target gene was normalized using the $\Delta\Delta C_q$ method (Livak and Schmittgen 2001) towards both the reference gene (Rp18) and negative control insects treated with nuclease-free water. A further negative control was performed with GFP.

Data analysis

Insect mortality data was corrected and normalized against the untreated control treatments using Abbott's formula (Abbott 1925). Dependent variables were subjected to Levene and Shapiro-Wilk tests in order to assess the homogeneity and normality of variance across the groups, respectively, and transformed whenever needed. Data were subjected to univariate analysis of variance following the GLM procedure with the relative expression level and percentage mortality as dependent variables and the target genes and the application rates as fixed factors. Multiple comparisons among treatments were carried out by using the Tukey–Kramer (HSD) post hoc test. The cumulative mortality response from the treated larvae and the respective controls were further analyzed using Kaplan–Meier survival analysis. The differences among the factors (i.e target genes or application rate) were tested for significance using the Mantel-Cox log rank test.

Differences in gene knockdown and mortality among the targeted genes and different doses were assessed using Tukey's test for multiple comparisons. All statistical analyses were performed using Microsoft Excel® 2016 and SPSS® 22.

Results

RNAi effects by dsRNAs injection

As confirmed by qRT-PCR, a significant dose dependent reduction in the expression of the three target genes was observed in both concentrations (2 and 5 µg) after 72 h of injection in larvae (Fig. 1A-C). At the lowest concentration (2 µg), the transcript levels were reduced of 27.60%,

258 34.50%, and 48.80% whereas at 5 μ g the gene expressions were reduced of 62.73%, 65.36%
259 and 75.42 % for AChE, nACHRs and RyRs respectively, compared with the negative control
260 (dsGFP).

261 The administration of dsRNAs caused a significant decrease in the survivorship on specimens
262 treated with the dsRNAs of selected genes, whereas both in the negative controls (GFP and
263 water) only few larvae (n = 1 specimen in both controls) did not reach the adult stage. The
264 survival analysis highlighted statistical differences (Log-Rank Mantel-Cox $\chi^2= 20.593$; df=7;
265 p=0.004) among the two controls (GFP and water) and the mortality observed in the larvae
266 injected with the dsRNA target genes.

267 In detail, the most effective treatment was the one where larvae were treated with 5 μ g of
268 dsRyRs; indeed in this treatment, 92.59 $\pm$ 5.73% specimens did not reach to the adult stage
269 (Figure 2). Conversely, the lowest mortality was achieved in larvae treated with 2 μ g of dsAChE
270 (7.40 $\pm$ 2.86% mortality). Overall, the mortality caused by the injection of each dsRNA was
271 always significantly dose dependent (AChE: F=16.200; df=1; p=0.016 – nACHRs: F=18.000; df=1;
272 p=0.013 – RyRs: F=9.800; df=1; p=0.035).

273 The dsRNAs injection had negative effects both in pre-pupal as well as in pupal stages weight
274 increase (Table 2). Both pre-pupae and pupae injected with 5 μ g of AChE dsRNA were lighter
275 than those treated with the lowest dsRNA application rate and the GFP control (pre-pupae:
276 F=17.028; df=2; p<0.001 – pupae: F=13.231; df=2; p<0.001). In contrast, larvae treated with
277 nACHRs dsRNA at both application rates (2 and 5 μ g), when reached the pre-pupal stage, were
278 statistically lighter than the control (F=31.051; df=2; p<0.001); instead, pupal weight decreased
279 proportionally to the dsRNA amount injected (F=20.579; df=2; p<0.001). The effects on weight

of RyRs dsRNA injection were dose dependent both in pre-pupal ($F=107.240$; $df=2$; $p<0.001$) as well as in pupal stages ($F=67.242$; $df=2$; $p<0.001$).

RNAi effects by dsRNAs delivered by roots

Larvae that fed on leaves that had been administered dsRNAs radically, highlighted a reduction of the expression of the three target genes (Figure 3). In all cases, the relative gene expression of the target genes were significantly lower ($p>0.05$) than the controls (GFP and water). The reduction of the transcript level ranged from 47% (RyRs) to 69% detected in the larvae that fed on plants treated with the dsRNA of nACHRs.

Also in these cases the dsRNAs had a significant effect on *T. absoluta* survival. The survival analysis showed no significant difference in the mortality between the two controls (GFP and water mortality = 1 specimen), whereas significant differences (Log-Rank Mantel-Cox $\chi^2=17.862$; $df=4$; $p=0.001$) were highlighted among the control and the mortality observed in larvae fed on plants in which the dsRNAs were delivered by root adsorption.

In detail, the mortality induced by the dsRNA delivered by plants, were significantly higher ($F=17.806$ $df=3$; $p=0.001$) in the silenced genes than in the GFP negative control (Figure 4). Multiple comparisons highlighted no significant differences among the three target genes ($p>0.05$). Overall the mortality registered in the dsRNAs treated plants ranged from 67.15% (RyRs) to 80.47% (nAChRs).

The weight of the pre-pupae fed on plants in which the dsRNAs of the target genes were administered (Table 3) was significant affected by the treatments ($F=10.032$ $df=3$; $p<0.001$). The specimens fed on plants treated with AChE dsRNA, had a pupal weight similar to the control

(GFP) ($p>0.05$) whereas, prepupae fed on plants administered both with nAChRs and RyRs dsRNAs were lighter than the control. Pupae (Table 3) developed in treated plants in all case weighted less than in the GFP negative control ($F=72.579$ $df=3$; $p<0.001$) with the lowest mean weight (1.71 ± 0.01 mg) recorded in pupae developed in plants treated with RyRs dsRNA.

Discussion

The invasive pest *T. absoluta* is considered in many parts of the world as one of the key pests of tomato. Insecticide resistance reported for several native and invaded areas (Biondi et al. 2018), has raised the demand to new control tools. In this scenario, RNAi can be the perfect candidate. However, serious efforts in outreach and education are needed to better inform the different stakeholders including the public and agricultural industry, leaders as well as decision makers in the regulatory and political communities to help expedite the release and adoption of RNAi products and technology (Andrade and Hunter 2016). Our study investigated the RNAi efficacy in silencing selected target genes in *T. absoluta* dsRNAs by injection and root delivery. All the target AChE, nAChRs and RyRs genes were successfully silenced by dsRNAs we synthesized and provided to the 3rd instar larvae. In the injection procedure, the administered dsRNAs was able to reduce the gene expression, inducing high mortality rate in the treated larvae. Both application rates have been shown to significantly reduce the gene expression while lower doses (i.e. 1 μ g) were ineffective for all the tested genes (data not shown). Also the weight of preimaginal stages was affected by the dsRNAs provided to

larvae; probably this aspect could have negative consequences on some biological parameters (fecundity, flight capacity, longevity, etc.) of adults.

Our target genes (AChE, nAChRs and RyRs) were selected for their importance and the involvement in nervous system and nerve transmission and for their effectiveness in RNAi experiments against other insect pests. Acetylcholinesterase (AChE) is a key enzyme in the insect central nervous system by hydrolysing the neurotransmitter acetylcholine into acetate and choline (Ye et al. 2017). Most insects have two different acetylcholinesterases (AChEs): AChE1 and AChE2 (encoded by *ace1* and *ace2* genes, respectively). Between these two AChEs, AChE1 has been suggested as the main catalytic enzyme based on its higher expression level (approximately 2- to 250-fold higher) and frequently observed point mutations correlated with insecticide resistance (Kim and Lee 2013). AChE gene silencing has been successfully tested on a number of insects such as *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae), *Blattella germanica* L. (Blattodea: Blattellidae), *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae), affecting the survival, the female reproduction, the embryo development and growth of offspring (Lu et al. 2012; Kumar et al. 2009; Revuelta et al. 2009; Saini et al. 2018). Our results, apart from reducing gene expression, prove the effectiveness of AChE gene silencing in *T. absoluta* by increasing mortality, and reducing the weight of both the prepupae and the pupae either by ingestion or radical absorption. In *H. armigera* the down-regulation AChE induced by dsRNA ingestion had negative effects, apart on the survival, also on the reproductive capacity of surviving adults whereas no effects were highlighted in pupal weight (Kumar et al. 2009).

nAChRs are ligand-gated ion channels that mediate fast synaptic transmission in the insect nervous system owing to the involvement of AChE in nerve transmission and other metabolic

346 processes (Jones et al. 2007). The $\alpha 6$ Nicotinic Acetyl-choline receptor subunit is the target of
347 two groups of insecticides (spinosins and neonicotinoids) but the role of individual nAChRs in
348 modulating responses to insecticides are not well known. (Rinkevich and Scott 2013) studying
349 the effects of the silencing of $\alpha 6$ nAChR in *Drosophila melanogaster* (Diptera: Drosophilidae)
350 and *T. confusum* concluded that this gene is not useful to understand the resistance mechanism to
351 spinosad. The same Authors attributed these limits, among the others, to intrinsic properties of
352 the target species. Our results, suggested that $\alpha 6$ nAChR is an effective target for RNA
353 silencing aimed at evaluating the effectiveness against *T. absoluta*. The corrected mortality
354 registered in the specimens injected with nAChRs dsRNA was higher than that recorded in the
355 specimens in which the target gene was AChE whereas, when the specific dsRNA was delivered
356 by root adsorption, the moth mortality reached about 80%.

357 Ryanodine receptors (calcium-induced calcium release channels) (RyRs) play an essential role in
358 most cell types. These receptors are located in the sarcoplasmic/endoplasmic reticulum
359 membrane mediating the release of intracellular Ca^{2+} during the excitation and contraction in
360 both cardiac and skeletal muscles (Hong et al. 2002; Lanner et al. 2010). Since calcium
361 signalling has a key role in most vital processes of insects, RYRs are molecular target for novel
362 diamide insecticides that have notably activity against Lepidopteran species (Sun et al. 2016).
363 Wan et al (2014) reported that oral supply of 0.5 μg of RyR dsRNA significantly reduced the
364 mRNA levels in *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae) larvae and adults
365 without affecting the mortality and the larval and adult movement. Yang et al. (2014) reported
366 similar results in *Sogatella furcifera* (Horváth) (Hemiptera: Delphacidae) in which the oral
367 administration of dsRNA of Ryanodine receptors significantly reduced the mRNA level of *SfRyR*
368 without affecting the mortality. In our study we used a higher amount of dsRNA; this could

explain the effect on mortality of insects treated at both 2 and 5 µg. We suppose that the dsRNA application rate play an important role since in our preliminary trials 1 µg of dsRNA did not affected the mortality pf treated specimens.

The RNA interference approach in Lepidoptera was first reported in 2002 when the effects of dsRNA on *Bombix mory* L (Lepidoptera: Bombycidae), *Hyalophora cecropia* L (Lepidoptera: Saturniidae) and *Spodoptera litura* Fabr. (Lepidoptera: Noctuidae) were reported (Bettencourt et al. 2002; Quan et al. 2002; Rajagopal et al. 2002). However, most studies about RNAi targeted to Lepidoptera were aimed to understand a number of systems, particularly developmental processes and immunity (Terenius et al. 2011). In this scenario, the studies on the application of RNAi method for the control of Lepidoptera and specifically on *T. absoluta* are limited. The first experiments on this pest were conducted by Camargo et al. (2016) that reported the V-ATPase and Arginine kinase gene silencing by dsRNAs. Camargo et al. (2016) investigated a delivery approach in which *T. absoluta* larvae fed in leaflets (not rooted) left to uptake the dsRNA from an aqueous solution.

The main objective of our experimentation was the potential use of effective dsRNAs delivered by root adsorption. To date the main methods of dsRNAs administration were injection into the haemolymph and oral delivery. Although these methods are valid for basic research, they are far from being applied under field conditions. To date the dsRNA root adsorption route has not yet been verified against *T. absoluta*. Both the delivery methods we used (injection and root adsorption) were successful in larvae gene silencing, increased mortality and reduced both the pre-pupal and pupal weight. The root adsorption delivery may have advantages over traditional methods (injection and oral delivery via artificial diet) as this method takes into account the entire plant system (root adsorption, dsRNA translocation in the plant and other variables,

difficult to study singularly, which may affect the degradation or bioavailability of dsRNA). Our results highlighted the ability of dsRNAs to migrate from water solution to internal parts of roots and then translocate in the plant. Despite we didn't measure the dsRNAs in plant, in larvae fed on treated plants a significant reduction were detected in the target gene expressions. The movement of dsRNAs in plant was studied by Camargo et al. (2016) by using labelled dsRNAs which were strongly detected both in leaflet petioles and blades 6 h after the treatment and throughout the leaf blade after 24h. Similarly to Camargo et al. (2016), our results, highlighted, 72 h after the treatments, a significant reduction in the transcript levels for all the target genes in larvae suggesting that the ability of plant to translocate dsRNAs is similar both in detached leaves as well as in rooted shoots.

Because the dsRNA root adsorption we adopted could well simulate what happened in the hydroponic crops, this delivery method could be considered as an insecticide treatment methods to be applied in the field. The potential of RNAi as a tool for insect pest control is widely recognized, since this approach has specificity and flexibility that cannot be matched in traditional control methods (chemicals, Biological control, GMO plants) (Scott et al. 2013). One of the major issues that limited the use of RNAi as a control tool is the cost related to the production and delivery of the effective dose of dsRNAs in field conditions. The ability of the dsRNA to be delivered through roots and the recent advances in dsRNA production technology allowing for the production of high doses at a reasonable cost, gives good reason to hope for its use on a large scale (Hunter et al. 2010, 2012; Scott et al. 2013).

Acknowledgment:

This research was partially supported by the Italian Ministry of Education, University and Research (MIUR) (PRIN project 2015 “BIOPICT”, 2015BABFCE; and through the ERA-NET action ARIMNET2 2015 call (project "Sustainable Tomato Production" - STomP). The University of Tabriz, Iran is gratefully acknowledged for its financial support to Sima Majidianii. We would like to express our deepest gratitude to Giulia Giunti and Davide Palermo for sharing their pearls of wisdom with us during the course of this research.

Author contribution statement

SM, VP, FL and OC conceived and designed the research. SM carried out the experiments. OC, LZ analyzed the data. SM, OC, LZ and FL wrote the MS. VP supervised the project. R.F.P.A helped supervise the project. S.R. and A.M. contributed to the final version of the manuscript. All authors read and approved the manuscript.

Ethical approval: This article does not contain any studies with human participants or animals performed by any of the authors.

Conflict of Interest: Authors declare no conflict of interests.

Figure captions

Figure 1 - Inhibition of the expression of three target genes after 72h of injection of 2 and 5 μg of dsRNA in *T. absoluta* third instar larvae. Values represent the mean $\pm$ SE of three replicates. Gene expressions were relative to the control GFP normalised to the internal control (18S rRNA). Dotted line represent the value of nuclease-free water. Different letters indicate significant differences among treatments (Tukey HSD post-hoc test; $p<0.05$).

Figure 2 – Effects of RNAi on *T. absoluta* mortality (mean $\pm$ SE) from third instar larvae to adults injected with 2 and 5 μg of dsRNA. Values represent corrected mortality (Abbott's formula); Different letters indicate significant differences between the two doses within the same treatment group (GLM UNIANOVA; $p<0.05$).

Figure 3 - Inhibition of the expression (mean $\pm$ SE) of three target genes in *T. absoluta* third instar larvae after 72h of feeding in rooted leaflets administered with 5 μg dsRNAs. Gene expressions were relative to the control GFP normalised to the internal control (18S rRNA). Dotted line represent the value of nuclease-free water. Asterisks indicate significant differences between each gene and the control (GLM UNIANOVA $p<0.05$).

Figure 4 – Effects of RNAi on *T. absoluta* mortality (mean $\pm$ SE) fed on plants administered with 5 μg of dsRNA. Values represent corrected mortality (Abbott's formula); Different letters indicate significant differences among the treatments (Tukey HSD post-hoc test; $p<0.05$).
