14 **Genetic improvement of wine yeasts for opposite adsorption activity of**
15 **phenolics and ochratoxin A during red winemaking**

16 **Caridi A., Sidari R., Pulvirenti A., Blaiotta G.**

17 **ABSTRACT**

18 The aim of this research was to acquire new strains of *Saccharomyces cerevisiae*
19 exhibiting opposite characteristics of cell wall adsorption: very high adsorption
20 activity towards the ochratoxin A, very low adsorption activity towards the
21 pigmented phenolic compounds contained in musts from black grapes. For this
22 purpose, starting from 313 strains of *Saccharomyces cerevisiae*, 12 strains were
23 pre-selected and used to obtain 27 intraspecific hybrids. Eleven crosses out of 27
24 were validated as hybrids; the best five hybrids were used in guided winemaking
25 at four Calabrian wineries. The employed experimental protocol has allowed to
26 select yeast strains for their different adsorption activity, improving the strains by
27 spore clone selection and construction of intraspecific hybrids. These results
28 suggest an efficacious way to improve the characteristics of interest in wine yeasts.

29 **KEYWORDS:** adsorption; clonal selection; hybrids; ochratoxin A; phenolics;
30 winemaking; yeasts

31

32 **1. Introduction**

33 The wine yeast selection constantly evolves and, consequently, new traits are proposed
34 in order to gain new specific wine characteristics (Ďurčanská et al. 2019). One of these -
35 the parietal adsorption activity - is notably different from yeast to yeast. These differences
36 are related to structural characteristics and chemical composition of the outermost layer
37 of cell wall and generate numerous oenological effects (Caridi 2006). The ability to
38 adsorb in winemaking unquestionably harmful substances - such as ochratoxin A (OTA)
39 - or commonly useful substances - such as pigmented polyphenolic compounds - is a
40 strain-dependent trait (Caridi and Sidari 2012). So, excluding the strains of
41 *Saccharomyces cerevisiae* able to adsorb both these compounds, it may be possible to
42 select, with specific protocols, yeast strains able to mainly adsorb OTA. In fact, while the

43 strains with high adsorbing activity are generally useful to produce white wines, the
44 strains with high adsorbing activity towards the OTA and low adsorbing activity towards
45 the pigmented polyphenolic compounds may be preferable to produce red wines.
46 Moreover, it was reported that the grape must composition affects the yeast adsorption
47 aptitude toward colored polyphenols and astringency of wines (Rinaldi et al. 2016; Sidari
48 and Caridi 2016). The greater or lesser phenolic adsorption on yeast cell wall influences
49 concentration and composition of phenolics in wine. Significant correlations between
50 yeast strain used for winemaking and phenolic content in wine were reported,
51 demonstrating that strain behavior can somewhat modify chromatic properties, phenolic
52 profile and antioxidant power of wines (Caridi et al. 2004, 2015, 2017a; Samoticha et al.
53 2019).

54 Grape must can contain different amounts of OTA, often due to the growth of
55 mycotoxin-producing molds at the end of grape ripening. Climatic and geographic
56 differences influence mold growth and OTA contamination of grapes. Nowadays, the
57 European legal limit for OTA concentration in wine is of 2 $\mu\text{g}/\text{kg}$ (Benito 2019). In
58 Europe, higher OTA levels were detected in wines originating from southern areas with
59 typically warmer climates. Consequently, the use of particular enological practices or
60 specifically selected wine yeasts - able to adsorb OTA during alcoholic fermentation -
61 was proposed to contrast this problem (Caridi et al. 2006; 2012; Cecchini et al. 2006;
62 Gambuti et al. 2005; Meca et al., 2010; Olivares-Marín et al. 2009; Petruzzi et al. 2015).
63 Literature data support our decision to perform a specific selection of wine yeasts able to
64 selectively remove OTA, so protecting both phenolics and color in red wines (Aponte and
65 Blaiotta 2016; Petruzzi et al. 2014).

66 Over years of isolation and clonal selection of newly isolated strains and their
67 descendants in single spore cultures, some strains with interesting characteristics were

68 identified. The next step may consist in the construction of intraspecific hybrids, starting
69 from the already selected strains, to control whether the required characteristics may be
70 enhanced this way.

71 The aim of this research was to acquire new strains of *S. cerevisiae* exhibiting
72 opposite characteristics in terms of cell wall adsorption: very high adsorption activity
73 towards OTA, very low adsorption activity towards the pigmented phenolic compounds
74 contained in the musts from black grapes. Therefore, *S. cerevisiae* strains were firstly
75 screened for main oenological traits; then, the best strains were further tested for their
76 phenolic and OTA adsorption ability. Lastly, hybrids obtained from the best strains were
77 tested in winemaking at wineries (Fig. 1).

78

79 **2. Material and methods**

80 **2.1. Pre-selection trials**

81 The starting point were 313 strains of *S. cerevisiae* supplied by the research groups of the
82 University of Modena and Reggio Emilia (UniMORE), University of Napoli (UniNA),
83 and University of Reggio Calabria (UniRC). The strains were pre-selected by evaluating:
84 (a) type of growth - to exclude flocculent strains - during grape must fermentation in test
85 tubes containing 10 mL of thermized (110°C for 10 min) and filtered (through sterile
86 gauze) grape must, according to Caridi et al. (2002); (b) acetic acid production - to
87 exclude high acetic acid producer strains - on Chalk agar at 30°C for three days according
88 to Lemaesquier et al. (1995); (c) H₂S production - to exclude high H₂S producer strains
89 - on BiGGY agar at 25°C for two days according to Nickerson (1953); (d) production of
90 spores typical of the genus *Saccharomyces* - to exclude non-spore and non-typical spore
91 producer strains - on acetate agar (anhydrous sodium acetate 10 g/L, agar 20 g/L) at 25°C
92 for 10 days according to Fowell (1952).

93 Based on the results obtained by the pre-selection trials, the yeast strains were
94 tested for their low adsorption activity of phenolics and high adsorption activity of OTA.
95 To study their aptitude to adsorb grape pigments, the yeast strains were grown in the
96 chromogenic grape-skin agar medium (Caridi 2013) and, after 10 days of anaerobic
97 incubation at 28°C, yeast biomass was photographed and the images were processed for
98 red, green, and blue components using Photoshop CS for Windows XP from Adobe.
99 Moreover, the strains were tested in micro-winemaking trials to confirm their low
100 aptitude to adsorb grape pigments and phenolics during fermentation. Black grapes of
101 *Gaglioppo* cultivar were given pre-fermentative maceration to extract pigments from
102 skins and seeds. They were destemmed, crushed and cold soaked at 0°C for three days,
103 performing a punch down twice per day. The must obtained after pressing (pH 3.50, °Brix
104 23) was divided in aliquots of 20 mL, immediately inoculated at 5% in triplicate with the
105 wine yeasts, and incubated at 20°C. The weight loss caused by CO₂ production after three
106 days of fermentation was determined according to Caridi (2003); so, the fermentation
107 vigor was expressed as g of CO₂ 100 mL⁻¹ of must. At the end of fermentation, wines
108 were diluted 1:5 (v/v) with a pH 3.5 buffer (citric acid monohydrate 0.1 M, Na₂HPO₄ 0.2
109 M) after centrifugation. The absorbance at 420, 520, and 620 nm was read using an
110 Anadeo1 spectrophotometer (Bibby Sterilin Ltd); the color intensity was calculated with
111 the following formula: $I = A_{420} + A_{520} + A_{620}$ (Glories 1984). The total phenolic
112 content was determined using the Folin-Ciocalteu's index according to Singleton and
113 Rossi (1965). Based on the results on strain aptitude to adsorb grape pigments and
114 phenolics, several strains were excluded. The remaining strains were further studied for
115 their aptitude to remove OTA from synthetic must (Yeast Nitrogen Base 6.7 g/L, tartaric
116 acid 5.0 g/L, malic acid 5.0 g/L, citric acid 0.2 g/L, dextrose 110 g/L, fructose 100 g/L,
117 and sucrose 7 g/L, pH 3.3) supplemented with 5 ppb of OTA, considering the percentage

118 of OTA removed. Yeast pre-cultures were prepared in YPD broth (yeast extract 10 g/L,
119 peptone 10 g/L, dextrose 20 g/L) at 28°C for 48 h. Tests were performed inoculating in
120 triplicate 10 mL of the synthetic must with 0.2 mL of the pre-cultures. The fermentations
121 were carried out at 25°C and after 28 days the natural OTA content of the wines was
122 determined by HPLC, expressing data in ppb (Meca, Blaiotta, and Ritieni 2010).

123

124 ***2.2. Sporulation and spore clone selection***

125 Parents and progenies were studied using the chromogenic grape-skin agar medium
126 and performing micro-winemaking trials to confirm their low aptitude to adsorb
127 grape pigments and phenolics during fermentation. The yeasts were grown at 28°C
128 for 2 days on YPD broth, solidified with 2% agar when required. Sporulation was
129 induced at 28°C for seven days on acetate agar. Ascospores were isolated on YPD
130 agar by a micromanipulator Singer MSM System series 300 manual. Ascus wall
131 was digested at 25°C for 20 min using zymolyase 20T - 10 mg/mL (Seikagaku,
132 Kogyo/Tokyo, Japan) diluted 1:9 with sterile distilled water. To make sure only
133 pure cultures were used, cells from a colony (monosporal cultures and potential
134 hybrids) of about 1 mm diameter were picked up and suspended in 25 µL of sterile
135 water. The cell suspension was purified through isolation by micromanipulator of
136 only one cell, to be sure obtaining a pure culture.

137 PCR reaction was performed directly on the colony by heat treatment (Ciani
138 et al. 2003) without extracting DNA and applying the PCR conditions described by
139 Mannazzu et al. (2002) and Mariangeli et al. (2004). The PCR amplicons were
140 analyzed by electrophoresis on a 1.4% agarose gel in 0.5 X TBE buffer stained with
141 ethidium bromide. The restriction fragments length polymorphism (RFLP) analysis
142 of the SED1 and AGA1 was performed with two restriction enzymes: *Hpa* II

143 (BioLabs, New England) for SED1 and *Alu* I (BioLabs, New England) for AGA1.
144 The reaction mix was incubated for 2 h and analyzed on 2% agarose gel.
145 Customized oligonucleotides were used to amplify some regions of the yeast
146 genome between the elements that provide an amplified sequence polymorphism,
147 useful in differentiating *S. cerevisiae* at the strain level (Ness et al. 1993; Legras
148 and Karst 2003). Amplification reactions were performed on a GeneAMP PCR
149 System 2004 thermal cycler (Applied Biosystems, Foster City, California), using
150 primers d12 and d21 and using the same experimental conditions set by Legras and
151 Karst (2003). The amplification products were analyzed by electrophoresis on 1.8%
152 agarose gel in 1X TBE buffer and visualized by UV light after ethidium bromide
153 staining.

154

155 **2.3. Hybrids production and molecular characterization**

156 Hybrids were obtained according to Boveri et al. (2012) and typed by molecular methods
157 including interdelta analysis and minisatellite markers (DAN4, AGA1, SED1, HSP150)
158 according to Boveri et al. (2012) and Aponte and Blaiotta (2016).

159

160 **2.4. Winemaking trials**

161 The control strain Zymaflore F15 (Laffort Oenologie, France) and the five best hybrid
162 strains were used in winemaking at four Calabrian wineries: 1) Azienda Agrituristica
163 Contessa, Lattarico (CS); 2) Azienda Vinicola Malaspina, Melito Porto Salvo (RC); 3)
164 Azienda Agricola Cosimo Murace, Bivongi (RC); 4) Azienda Agricola Fratelli Zagarella,
165 Arghillà (RC). Therefore, grape musts of the following cultivars: *Gaglioppo*, *Magliocco*,
166 *Malvasia nera*, and *Nerello calabrese* were used.

167

168 *2.5. Analyses of the wines*

169 The wines produced were analyzed for the absorbance at 420, 520, and 620 nm -
170 indicating the yellow, red, and blue color, respectively - the color intensity, the total
171 phenolic and the OTA content using the above reported methods. In addition, the
172 experimental wines were analyzed by HPLC on a Gilson 307 Series HPLC system
173 equipped with a refractive index detector (RID 133, Gilson) and using an MetCarb68H
174 column (6.5 300 mm, Varian) as reported by Aponte and Blaiotta (2016). The flow rate
175 was 0.4 mL/min and the mobile phase was 0.01 N H₂SO₄. The injection volume of mixed
176 standards was 20 mL. The temperature of the column was set at 65°C. The identification
177 of acetic, citric, tartaric, malic, and succinic acids and of glycerol and ethanol was carried
178 out by comparing retention times with those of standards (wine analysis stock solutions
179 I, II and IV, Fluka) under the same HPLC conditions. Quantitative determination was
180 performed using the external standard method.

181

182 *2.6. Statistical analysis*

183 Data - two replicates - were subjected to statistical analysis using StatGraphics Centurion
184 XVI for Windows XP (StatPoint Technologies, Inc., USA) according to Fisher's LSD
185 (Least Significant Difference) ($p < 0.05$).

186

187 **3. Results**

188 *3.1. Pre-selection trials*

189 To increase the biodiversity of the yeast strains from which to start the research, we have
190 found the candidates for the final selection by performing different screenings of many
191 wine yeast strains isolated from different territories of the Mediterranean basin.

192 A first group of candidates was provided by the UniMORE research group. Ten

193 strains were obtained by the screening of 111 yeast strains isolated from: a) grapes of the
194 *Carricante*, *Grecanico*, and *Nerello mascalese*, cultivars, grown in the Sicily region
195 (Italy), b) grapes of the *Grecanico*, *Tempranillo* and *Touriga national* cultivars, grown in
196 the Penedès and La Rioja regions (Spain), c) grapes of the *Tinta rorizi*, *Touriga franca*,
197 and *Touriga national* cultivars grown in Portugal (data not shown).

198 A second group of candidates was provided by the UniNA research group. Ten
199 strains were obtained after screening of 118 yeast strains isolated from grapes of the
200 *Catalenesca del Vesuvio*, *Gragnano*, *Moscato di Saracena*, and *Magliocco Canino*
201 (Pollino DOC area) cultivars grown in the Campania (Italy) and Calabria (Italy) regions
202 (data not shown).

203 A third group of candidates was provided by the UniRC research group. Seven
204 strains were obtained after screening of 84 yeast strains isolated from grapes of the *Greco*
205 *bianco*, *Inzolia*, *Magliocco*, *Nerello calabrese*, and *Pecorello* cultivars grown in the
206 Calabria (Italy) and Sicily (Italy) regions (data not shown).

207

208 **3.2. Sporulation and spore clone selection**

209 Through dissection with Singer micromanipulator and after controlling the viability of
210 the spores, 280 monosporal cultures were obtained from the pre-selected 27 strains: 113
211 descendants from the 10 candidates of UniMORE, 99 descendants from the 10 candidates
212 of UniNA, and 68 descendants from the seven candidates of UniRC. In order to highlight
213 the segregation of the desired traits, the monosporal cultures obtained were subjected to
214 the same screening tests performed on the parental strains. As result of this screening,
215 four monosporal cultures for each site were chosen for classic genetic improvement by
216 using the hybridization technique (data not shown).

217

218 **3.3. Hybrids production and molecular characterization**

219 The hybridization technique is understood as a genetic improvement technique.
220 Consequently, it is necessary to verify the variations of the phenotypic characteristics of
221 interest of the hybrid. So the molecular investigations give us confirmation of the
222 crossing, while the phenotypic ones give us confirmation of the improvement or, on the
223 contrary, of the possible loss of the traits of interest. Ultimately, the hybrid can be better
224 or worse than the parents. Consequently, the term "genetic improvement" was adopted
225 since the hybridization done with spores may effectively improve the yeasts for the
226 studied traits. Obviously, the technique used is a classic genetic improvement technique.

227 The crossings made obtained a total of 27 hybrid strains. However, only 11
228 hybrids could be validated by analyzing them and the corresponding parents by molecular
229 markers -RFLP analysis of the SED1 and AGA1 minisatellites (Boveri et al, 2012).

230 In order to better characterize the 11 hybrids, additional molecular markers were
231 analyzed (Table 1). The results of the genotypic analysis by different molecular markers
232 showed that the numerous hybridization attempts led to the obtainment of 11 different
233 hybrids; two hybrids - RC029A-1D x RC039C-1C (4) and RC029B-1C x RC039C-1C
234 (7) - coming from the same parents showed identical molecular markers.

235 The 11 hybrid strains obtained were subjected to phenotypical analysis (Table 2)
236 to choose the best five hybrid strains, which were used to perform winemaking at the four
237 wineries. The hybrids exhibited similar acetic acid production on Petri plates but at the
238 end of the winemaking one of them - strain RC029A-1D x RC039C-1C (4) - exhibited a
239 too high value (0.452 g/L of acetic acid) and was excluded. Eight out the 11 hybrids
240 produced a low or medium content of sulphur compounds; so three strains - NA014C-1D
241 x RC039C-1C (3), RC026C-1C x RC039C-1C (9), and RE049B-1A x RC039C-1C (9) –
242 were excluded due to their too high sulphur compounds production. The OTA removal

243 ranged from 7.24 to 58.50 %; so, two strains - NA015A-1B x NA093B-1C (2) and
244 NA015A-1B x RC039C-1C (5) - that exhibited the lowest adsorption of the OTA were
245 excluded.

246

247 *3.4. Analyses of the wines*

248 Table 3 reports the analytical traits of the wines produced at the winery Contessa using
249 black grapes of the cultivar *Magliocco*. Compared to the control wine - produced using
250 the wine yeast Zymaflore F15 - all the five hybrids produced wines with lower content of
251 OTA. Strain RC029B-1C x NA093B-1C (6) seems to be preferable since produced wine
252 with higher contents in ethanol and tartaric acid and with the lowest content in acetic acid.

253 Table 4 reports the analytical traits of the wines produced at the winery Zagarella
254 using black grapes of the cultivar *Malvasia nera*. Compared to the control wine, all the
255 five hybrids produced wines with significantly lower content of OTA and significantly
256 higher content in polyphenolic compounds (Folin-Ciocalteu's index). Strain RC029A-1D
257 x RE078C-1C (4) seems to be preferable due to the higher contents in ethanol, tartaric,
258 malic, and succinic acids, the significantly highest absorbance at 520 nm and color
259 intensity, and to the lowest content in acetic acid.

260 Table 5 reports the analytical traits of the wines produced at the winery Malaspina
261 using black grapes of the cultivar *Gaglioppo*. Some analyses of the wine produced with
262 the hybrid RC029A-1D x RE078C-1C (4) are missing because they were not detected
263 (see "nd" in the table); this has no consequence on the conclusions drawn. Compared to
264 the control wine, strain RE049B-1A x NA093B-1C (5) seems to be preferable due to the
265 higher content in ethanol, higher absorbance at 520 nm and color intensity, higher content
266 in polyphenolic compounds (Folin-Ciocalteu's index), and to the lowest content in OTA.

267 Table 6 reports the analytical traits of the wines produced at the winery Murace

268 using black grapes of the cultivar *Nerello calabrese*. Some analyses of the wines produced
269 with the hybrids RC029A-1D x RE078C-1C (4) and RC029B-1C x RC039C-1C (7) are
270 missing because they were not detected (see "nd" in the table); in addition, for the same
271 reason, the acetic acid content is missing for all the wines. This has no consequence on
272 the conclusions drawn. Compared to the control wine, strain RC029B-1C x RE078C-1C
273 (4) seems to be preferable due to the highest content in ethanol and tartaric acid, the
274 significantly highest absorbance at 520 nm and color intensity, higher content in
275 polyphenolic compounds (Folin-Ciocalteu's index), and to the lowest content in OTA.

276 It is interesting to note that in the different winemaking trials the hybrids
277 performed differently; therefore, the importance of a correct and specific strain selection
278 is validated.

279

280 **4. Discussion**

281 The wine industry is constantly searching for yeast strains that could result in the
282 production of wine with better sensory and color properties; however, when selecting
283 yeasts, it should be taken into account that possible enhancement of a specific wine
284 characteristic could have a detrimental effect on the other wine properties (Topić Božič
285 et al. 2019). Sidari et al. (2007) demonstrated that yeast starter can induce differences in
286 wine color. In some circumstances, this is due to the wine color adsorption phenotype, an
287 inheritable quantitative trait loci of wine yeasts (Caridi et al. 2007). Monagas et al. (2007)
288 conducted a study on the influence of *S. cerevisiae* yeast strains on the anthocyanin,
289 pyranoanthocyanins and non-anthocyanin phenolic compounds of red wines; the results
290 showed that anthocyanins were the compounds most affected by the yeast strains,
291 independently of the grape variety.

292 The main yeast selection criteria to improve wine color include: 1) the ability to
293 enhance wine color via the metabolic formation of stable pigments, e.g., vitisins and
294 vinylphenolic pyranoanthocyanins, and the scant adsorption of anthocyanins by the yeast
295 cell wall; 2) the absence of β -glucosidase activity, to prevent color degradation; 3) the
296 facilitation of colloidal stabilization in red wines by allowing over-lees aging, to help
297 stabilize color (Suárez-Lepe and Morata 2012). Meca et al. (2010) showed that yeast
298 adsorbed the mycotoxin on the external and internal part of the cell. Moreover, OTA is
299 mainly adsorbed during yeast exponential grow phase and in some cases, depending on
300 strain, again released in wine (Aponte and Blaiotta 2016). This phenomenon could be due
301 to the premature autolysis of some yeast strains.

302 Yeast cells adsorption activity is one of the proposed mechanisms to remove both
303 colored phenols and OTA (Bejaoui et al. 2004; Moruno et al. 2005). Other authors have
304 proposed OTA degradation pathway (Angioni et al. 2007). We propose, for the first time,
305 to control red winemaking using selected hybrid yeast strains in order to remove OTA
306 and not remove colored phenols. The results are of interest as OTA content in wines has
307 a legal limit - at least in Europe - and the most common corrective techniques to reduce
308 it - fining agents like active carbon or amicrobial filtration - are efficient but possess
309 important undesirable collateral effects, such losses of color and aroma. Frequently, prior
310 to bottling, the wine is treated by amicrobial filtration, in which it passes through a battery
311 of filters and goes directly to the warehouses of the cellar; this way up to 80% of OTA is
312 usually removed. The five hybrids were chosen considering not only the OTA adsorption
313 parameter (47-53% in synthetic must supplemented with 5 ppb of OTA) but taking also
314 into account and balancing the other screening parameters, for example color intensity.
315 All the wines produced using the five hybrids always exhibited no detectable OTA or
316 OTA content under the legal limit. One treatment (hybrid yeast) does not exclude the

317 other (amicrobial filtration) as one takes place during fermentation and the other during
318 stabilization.

319 The most delicate work was to develop a certain system to confirm that the strains
320 obtained after micromanipulation were truly hybrids deriving from the two parents. Being
321 parents of the same species, the techniques normally applied are not effective. With
322 regard to the validation of the effective establishment of intraspecific hybrids deriving
323 from the crossbreeding of monosporal cultures, selected on the basis of the characteristics
324 “*very high adsorption of the OTA*” and “*very low adsorption of the colored phenolic*
325 *compounds*”, we have decided to use the comparison of the polymorphism of
326 minisatellite-like regions contained in the two genes SED1 and AGA1. Both genes
327 encode components of the cell wall structure, the first for membrane glycoproteins, the
328 second for anchoring the α -agglutinin subunit to membrane components. The
329 minisatellite-like regions, contained in the two genes, were studied and developed in
330 laboratory protocols, adopting this system to highlight the differences in polymorphism
331 in both the amplified and restriction mapping for identification and characterization at the
332 level of strain and species of “*wild*” yeasts. It was previously verified that for the genes
333 tested there are numerous allelic variants of the same minisatellite-like regions, found
334 both by directly studying the wild-type karyotype, and the monosporal cultures deriving
335 from the same sample (Boveri et al. 2012). This last data is interesting for our research,
336 as we work with monosporal crops and, therefore, suppose that there is an increase in
337 polymorphism, which can be used to compare different profiles. We hypothesized that
338 sexual recombination - hybridization mechanism - generates an acquisition of both
339 amplification structures deriving from the two parental strains. The use of the
340 polymorphism of the SED1 gene was not sufficient for all the couples to be hybridized.
341 So, in the same way we proceeded to study the amplified of the AGA1 gene to find

342 differences between the missing couples. This was possible because all the hybridization
343 pairs have either SED1 or AGA1. Even with the AGA1 gene, the actual recombination is
344 already denoted by comparing the amplified and, subsequently, always in the same
345 modalities and principles of recombination, but with a different restriction enzyme (AluI),
346 also by comparing the restriction profiles. Both the study of the polymorphism of the
347 SED1 gene and that of AGA1 are an excellent and easy way to set up tool in the procedure
348 and in the reading of electrophoretic profiles, for the validation of intraspecific hybrids.
349 Given the importance of the yeast cell wall composition in the adsorption process of
350 colored phenolic compounds (Mazauric and Salmon, 2006; Morata et al. 2003; Sidari et
351 al. 2007; Caridi et al. 2017b) and OTA (Chen et al. 2018), and given the direct implication
352 of the SED1 and AGA1 genes in some of the membrane components, it is assumed that
353 the choice of these genes as molecular targets for the validation of intraspecific hybrids
354 is of interest.

355 The natural variability of yeasts for the studied traits may be exploited to obtain a
356 further enhancement of the adsorption/non-adsorption activity of wine yeasts. However,
357 the trend of the yeast adsorption performance is that strains that remove more OTA are
358 the same that adsorb more color and phenolics from wine. Consequently, the best strains
359 for red winemaking obtained with the present selection possess intermediary adsorption
360 characteristics. The inheritable nature of the adsorption of wine color and OTA were
361 analyzed on descendants derived from wine strains of *S. cerevisiae*; investigation on the
362 progeny demonstrated that adsorption of wine color and adsorption of OTA are polygenic
363 inheritable quantitative traits loci, partially and interdependently correlated to color and
364 phenolic content of wines. This may justify the employment of genomic strategies for
365 genetic improvement of the strains.

366

367 **5. Conclusion**

368 The employed experimental protocol has allowed to select yeast strains for innovative
369 characteristics connected to their different adsorption activity, allowing to improve the
370 strains by spore clone selection and construction of intraspecific hybrids. The results
371 encourage to continue in this direction to enhance the traits of interest. Taking into
372 account the results, it is possible to affirm that the choice of the most promising strain
373 depends also on the grape's cultivar used. The hybrid RC029B-1C x NA093B-1C (6) is
374 the best strain in the winemaking of *Magliocco* and *Gaglioppo* cultivars while the hybrids
375 RC029A-1D x RE078C-1C (4) and RE049B-1A x NA093B-1C (5) is the best strains in
376 the winemaking of *Malvasia nera* and *Nerello calabrese* cultivars. The proposed
377 methodology efficiently removes OTA and does not possesses the collateral effects - such
378 as loss of aroma and color - reported to other methodologies employed at industry level
379 to deal with the problem.
