#### 27 Abstract

28 The aim of this study was to evaluate the effects of 10 Starmerella bacillaris strains inoculated as 29 planktonic or biofilm-detached cells on the chromatic characteristics of Montepulciano d'Abruzzo 30 wine. Wines inoculated with biofilm-detached cells of *St. bacillaris* were characterized by a higher 31 content of glycerol and viable yeast cells and a lower content of ethanol than those obtained with 32 planktonic cells. Pyruvic acid content ranged from 45.99 mg/L to 48.19 mg/L and from 41.13 mg/L 33 to 45.9 mg/L in wines fermented with biofilm-detached and planktonic cells, respectively. Wines 34 obtained with biofilm-detached cells showed levels of anthocyanins ranging from 506.8 mg/L to 35 659.9 mg/L, while those fermented with free cells of St. bacillaris ranged from 518 mg/L to 612.6 36 mg/L. Similarly, the content of polyphenols was higher in wines inoculated with biofilm-detached 37 cells. The different amounts of these compounds resulted in differences in the wine's color. Wines 38 obtained with biofilm-detached cells of St. bacillaris had lower b\* and h\* values than those obtained 39 with planktonic cells. These wines also showed higher a\* values, indicating the presence of a stronger 40 red color than the others, and lower clarity (L\*). Moreover, the data obtained highlighted that it is 41 possible to predict the color of young wines from must measurements. Further studies will be done 42 to evaluate the role of other non-Saccharomyces yeasts, grown under different aggregation states, in 43 the definition of wine color.

44 Keywords: *Starmerella bacillaris*; biofilm-detached cells; planktonic cells; anthocyanins; wine 45 color; Montepulciano d'Abruzzo

#### 1. Introduction

53 The process of wine production encompasses a broad range of microorganisms with distinct functions 54 (Jolly, Varela, & Pretorius, 2014). Yeasts and lactic acid bacteria (LAB) are the main components of 55 the wine microbial consortium, and are known to exhibit either positive or negative effects (Jolly et 56 al., 2014). Although *Saccharomyces cerevisiae* is commonly the dominant species, it is widely 57 acknowledged that a diverse range of non-*Saccharomyces* yeasts are also present in both spontaneous 58 and inoculated wine fermentations. Non-*Saccharomyces* yeasts play a significant role in the release 59 of secondary metabolites contributing to the development of wine's flavor profile (Padilla, Gil, & 60 Manzanares, 2016). In fact, these yeasts are involved in the production of esters, higher alcohols, 61 acids and terpenes (for a review see Padilla et al., 2016). These compounds are essential in the 62 definition of wine organoleptic properties and play an important role in consumer preference 63 (Madžgalj et al., 2022).

64 During the fermentation process a metabolic interplay between *S. cerevisiae* and non-*Saccharomyces* 65 yeast species has been described, indicating that they do not merely coexist in a passive manner (Jolly 66 et al., 2014). For instance, mixed fermentation of *S. cerevisiae* and *Starmerella bacillaris* (also known 67 as *Candida zemplinina*) allow to enhance fermentation kinetics while minimizing the production of 68 ethyl acetate and acetic acid (Tofalo et al., 2016). This non-*Saccharomyces* yeast is commonly 69 isolated from grapes, musts, soil, fruits, and insects, and exhibits noteworthy oenological traits e.g., 70 elevated glycerol production, reduction of acetic acid and ethanol concentration, enhanced aroma 71 complexity, capacity to thrive in high sugar concentrations, and fructophilic tendencies (Tofalo et al., 72 2012; Russo et al., 2020; Nadai, Giacomini, & Corich, 2021; Nisiotou et al., 2018). Moreover, the 73 inoculation of *St. bacillaris* adhered on oak chips allowed to improve the color of Trebbiano 74 Abruzzese wines improving its green/yellow nuances (Perpetuini et al., 2023). The impact of yeasts 75 on wine color can be attributed to three distinct mechanisms. Firstly, yeasts can release metabolites 76 that can contribute to the stabilization of red wine color and enhance the content of stable pigments 77 (Escott, Feuillat, Dulau, & Charpentier, 2018). Secondly, yeasts possess enzymatic activities such as 78 glycosidase and pectinase which favor polyphenols extraction form grapes. Finally, yeast cell walls 79 have the ability to adsorb phenolic compounds, particularly anthocyanins and tannins, resulting in a 80 significant reduction in red wine color and astringency (Tofalo, Suzzi, & Perpetuini, 2021). This 81 phenomenon is strain dependent and not yet completely understood. It probably depends on cell wall 82 surface structure and composition being apolar anthocyanins better adsorbed than polar ones. 83 Moreover, the impact of yeasts on wine color is also related to the production of acetaldehyde and 84 pyruvic acid (Morata et al., 2012; Belda et al., 2017). This activity is strain dependent and is notably 85 pronounced in non-*Saccharomyces* yeasts. It has been observed that *Schizosaccharomyces pombe* 86 released a greater concentration of pyruvate compared to *Saccharomyces cerevisiae*. In comparison 87 to *S. cerevisiae, Torulaspora delbrueckii* is known to generate a reduced quantity of acetaldehyde. 88 Therefore, the identification of non-*Saccharomyces* yeast strains exhibiting optimal pyruvate and 89 acetaldehyde production for co-fermentation with *S. cerevisiae* could serve as a viable approach to 90 stabilize wine color (Morata et al., 2012; Belda et al., 2017). It seems that the augmentation of 91 metabolic activity and survival time of non-*Saccharomyces* yeasts can lead to a successful mixed 92 culture fermentation also in terms of wine color.

93 Recently, there has been a growing interest in the biofilm lifestyle of yeast and bacteria. Biofilms can 94 be defined as a community of microorganisms that are enclosed by an extracellular matrix composed 95 of extracellular polymeric substances that are generated by the microorganisms themselves (Donlan 96 & Costerton, 2002). Recent studies have reported that biofilm-detached cells are characterized by 97 phenotypes and properties similar to sessile cells and different from those of planktonic ones 98 (Perpetuini et al., 2021, Perpetuini, Tittarelli, Perla, & Tofalo, 2022; Bastard et al., 2016). Therefore, 99 some authors suggested the use of sessile cells, as well as biofilm-detached cells, to shape the 100 oenological parameters of red and white wines (Perpetuini et al., 2021; 2023; Bastard et al., 2016; 101 Pannella et al., 2020). However, to date, little information is available on the influence of biofilm 102 detached yeasts on the chromatic characteristics of wine. Therefore, the aim of this study was to 103 evaluate the impact of biofilm-detached and planktonic cells of *St. bacillaris* in co-colture with *S.*104 *cerevisiae* on the chromatic characteristics of Montepulciano d'Abruzzo wine.

105

#### 106 2. Materials and methods

#### 107 2.1 Sampling site

108 Must samples *Vitis vinifera* cultivar (cv.) Montepulciano were kindly provided by a cellar located in 109 Orsogna (Chieti, Abruzzo, Italy). Vineyards (42°13′ 01.5″N; 14°14′ 43.6″E), 403 m elevation, with 110 calcareous, clayey soil received no irrigation, and were subjected to organic in accordance with Reg. 111 EC 834/2007 (EC, 2007) since 2012. In particular, the pest management was achieved only through 112 copper/sulphur-based products.

113 The *Vitis vinifera* cultivar (cv.) Montepulciano is the most important red variety of Abruzzo region, 114 with over 35,000 ha of vineyards planted mainly along the Adriatic Coast. It is used for the production 115 of high-quality red wines like Montepulciano d'Abruzzo Colline Teramane, and Terre Tollesi (or 116 Tullum) wines which gained the DOCG (Designation of Controlled and Guaranteed Origin) 117 recognition.

#### 118

#### 119 2.2 Strains origin

120 Ten strains of *St. bacillaris* (SB1, SB3, SB5, SB7, SB8, SB9, SB10, FUC9, FUC16, and FUC17) and 121 a strain of *S. cerevisiae* (SRS1) were used in this study. All strains belong to the Culture Collection 122 of the Microbial Biotechnology Laboratory (Department of BioScience and Technology for Food, 123 Agriculture, and Environment – University of Teramo, Italy) and were previously characterized 124 (Suzzi et al., 2012; Tofalo et al., 2016; Perpetuini et al., 2021). All strains were isolated from 125 Montepulciano d'Abruzzo grapes, with the only exception of FUC9, FUC16, and FUC17 which were 126 isolated from Nero Antico di Pretalucente grapes. The strains were cultivated under aerobic 127 conditions at 28°C for 48 hours on YPD medium, which consists of 1% w/v yeast extract, 2% w/v 128 peptone, and 2% w/v glucose, as per standard practice. The strains were preserved at a temperature 129 of -80°C in YPD broth supplemented with glycerol (Sigma-Aldrich, Milan, Italy) at a final 130 concentration of 20% v/v.

#### 131

#### 132 2.3 Small scale vinification

133 Must from Montepulciano grapes was obtained after 3 days of cryomaceration at 4 °C in contact with 134 skins and seeds, was divided in aliquots of 400 mL, and pasteurized (Caridi, Sidari, Kraková, Kuchta, 135 & Pangallo, 2015). Fermentations were carried out in 500 mL Erlenmeyer flasks closed with a Müller 136 valve filled with sulfuric acid. Each flask contained 400 mL of the must obtained as described above 137 (248 g/L – 24.6 °Bx of fermentable sugars, 7.67 titratable acidity, pH of 3.4). The fermentation was 138 carried out under static conditions at 25°C. The flasks were inoculated with pre-cultures grown in the 139 same must for 48 h. Strains were co-inoculated at a final concentration of 6 Log CFU/mL. The cell 140 concentration was determined by counting under light microscopy. *Starmerella bacillaris* strains 141 were inoculated both as planktonic and biofilm-detached cells. Biofilm-detached cells were prepared 142 as previously described (Perpetuini et al., 2022). Briefly, biofilms were formed inoculating cells in 143 flat-bottom 6-well cell culture plates (Costar, Corning, NY, USA). After 7 days sessile cells were 144 detached using a sterile cell scraper (Perpetuini et al., 2022). These cells are referred as biofilm 145 detached cells and used for further experiments.

146 The kinetics of fermentation were assessed on a daily basis through the observation of weight
147 reduction resulting from the emission of CO2. Once a stable weight was reached, the fermentation
148 process was considered as ended. Three biological and three technical replicates were conducted.
149

### 150 2.4 Viable yeasts count

151 Serial dilutions were prepared in physiological solutions (NaCl 0.85% w/v). Cell suspensions were 152 plated on WLN agar, which allows the visual differentiation of *St. bacillaris* and *S. cerevisiae* yeast 153 species. Plates were incubated at 28 °C for 3–5 days before counting. In this medium, *St. bacillaris* 154 forms flat, light to intense green colonies, while *S. cerevisiae* forms creamy white colonies, with light 155 shades of green on the top facilitating the concurrent enumeration of both species during the 156 fermentation process. Plate count was performed after 7 days of alcoholic fermentation (T7) and at 157 the end of fermentation (Tf). All analyses were performed in triplicate.

158

#### 159 2.5 Main oenological parameters

160 FOSS WineScan<sup>™</sup> FT120 rapid scanning Fourier Transform Infrared Spectroscopy with FOSS 161 WineScan software version 2.2.1 was used to analyse the main physicochemical parameters. 162 Previously, the equipment was calibrated using wine samples tested according to established OIV 163 protocols (OIV, 2023). The pH was determined using a pH meter. Pyruvate, polyphenols, and 164 anthocyanins were determined enzymatically using commercial kits from Steroglass (Perugia, Italy) 165 according to the manufacturer's instructions. Acetaldehyde concentration was determined by gas 166 chromatography with a flame ionization detector (GC-FID) using Agilent Technologies 6850 167 equipment (Palo Alto, CA), according to Morata et al. (2015).

#### 168

#### 169 2.6 Wine color analysis

170 Wine color analysis was carried out using a colorimeter (Minolta, Chroma Meter CR-5). Clarity (L\*), 171 red/green color component (a\*), and blue/yellow color component (b\*), and their derived magnitudes, 172 chroma (C\*), and tone (h\*), were determined using glass cuvettes with a path length of 0.2 cm after 173 clarification of the samples by centrifugation (OIV, 2023). The color of wines obtained with 174 planktonic cells and biofilm-detached cells was compared, and the color difference was expressed as 175  $\Delta E = [(\Delta L)2 + (\Delta a^*)2 + (\Delta b^*)2] \frac{1}{2}$  (Ayala, Echavarri, & Negueruela, 1997).

176

#### 177 2.7 Confocal laser scanning microscopy

178 Biofilms were visualized through the utilization of confocal laser scanning microscopy (CLSM) with 179 the Nikon A1-R confocal imaging system, which was operated through the Nikon NIS-Elements 180 interface (Version 4.40, Nikon Corp., Tokyo, Japan). The analyses were conducted in triplicate

#### 181 2.8 Statistical analysis

182 The ANOVA test was performed using XLStat 2014 software (Addinsoft, New York, NY, USA) and 183 was applied on the oenological parameters, the content of polyphenols, anthocyanins, pyruvic acid, 184 and acetaldehyde, and the chromatic characteristics of wine in order to identify the significant 185 differences. The Bonferroni correction was applied. The Pearson's Correlation matrix analysis was 186 performed using XLStat 2014 software considering the content of anthocyanins, polyphenols, 187 glycerol, ethanol, pyruvic acid, acetaldehyde, the number of cells and the chromatic charactristics of 188 wines.

189 Moreover, a machine learning (ML) framework to estimate the wine color from anthocyanins, 190 polyphenols, the number of viable yeast cells, pyruvic acid, and acetaldehyde was developed. 191 Particularly, a Support Vector Regressor (SVR) with a radial basis function kernel was used to 192 estimate, independently, the L\*, a\*, and B features, using as input anthocyanins, polyphenols, the 193 number of viable yeast cells, pyruvic acid, and acetaldehyde. The input features were normalized (z 194 score), and the generalization performance of the model was tested employing a nested cross 195 validation (nCV). The nCV approach involves partitioning the available data into distinct folds, and 196 subsequently training the model in an iterative and nested manner on all folds except for one. The 197 outer loop and inner loop serve distinct purposes in the model evaluation process. While the outer 198 loop is responsible for estimating the model's performance across iterations, the inner loop is tasked 199 with identifying the optimal hyperparameter through validation. In this study, a 5-fold CV was 200 performed. The performance of the models was evaluated considering the correlation coefficient 201 between the measured and predicted variables.

202

## 203 3. Results and discussion

204 The microbial metabolism is influenced by the lifestyle of microrganisms: sessile cells, as well as 205 biofilm-detached cells, frequently express phenotypes that are different from their planktonic 206 counterparts (Bastard et al., 2016; Pannella et al., 2020). Recent studies reported the ability of *St.*  207 *bacillaris* to form biofilms on different abiotic surfaces, revealing that sessile and planktonic cells 208 can influence the characteristics of wines in different ways (Perpetuini et al., 2021; 2022). In 209 particular, wines fermented with sessile cells allowed to obtain wines with higher concentrations of 210 esters and glycerol and with a different sensory profile. In order to better understand the contribution 211 of biofilm-detached cells to wine characteristics, in this study, the effect of biofilm-detached cells 212 and planktonic cells on the chromatic characteristics of Montepulciano d'Abruzzo wine was tested. 213

#### 214 3.1 Determination of biofilm forming ability

215 The biofilms formed by *St. bacillaris* strains were visualized, for the first time, by CSLM. CSLM 216 analysis revealed that all strains were able to form biofilm, in a strain-dependent way. Fig. 1 showed 217 a three-dimensional reconstruction of *St. bacillaris* biofilms resulting from the compilation of a series 218 of individual xy sections taken across the z axis. The images showed a biofilm organized in a 219 monolayer of sessile cells surrounded by an extracellular polysaccharide-like substance. Although, 220 the biofilm did not cover the entire surface of the glass, the cells adhered, flattened, and produced 221 extracellular material that bonded them to the surface, after which they finally organized themselves 222 in microcolonies (Fig. 1).

#### 223

#### 224 3.2 Oenological parameters and yeast viability

225 The presence of *S. cerevisiae* allowed the fermentation process to end after 15 days. However, when 226 *St. bacillaris* was inoculated as biofilm-detached cells, a slower fermentative activity was observed 227 (Supplementary Figure 1). In fact, the trials inoculated with *S. cerevisiae* and biofilm-detached cells 228 of *St. bacillaris* showed a lower fermentative power, evaluated as  $CO_2$  evolution (g/100 ml) after 2 229 days of fermentation. The  $CO_2$  evolved in trials inoculated with *S. cerevisiae* and planktonic cells of 230 *St. bacillaris* ranged from 1.6 g CO2/100mL to 5.1 g CO2/100mL, while in trials inoculated with *S.* 231 *cerevisiae* and biofilm-detached cells of *St. bacillaris* from 0.88 g  $CO_2/100$ mL to 3.65 g  $CO_2/100$  mL 232 after 2 days. This slower fermentation ability could be related to the metabolism of sessile cells or 233 biofilm-detached cells, which are characterized by a different metabolism, e.g., in terms of metabolite 234 production, than their planktonic counterparts (Bojsen et al., 2012). Probably, these differences could 235 slow down the fermentation process, influencing the interactions between St. bacillaris and S. 236 cerevisiae strains. Rossouw et al. (2015, 2018) showed that changes in adhesion properties of S. 237 cerevisiae significantly affected the survival of other yeast species. Probably, this evidence could be 238 true also for St. bacillaris strains used in this study. Moreover, the inoculation of biofilm-detached or 239 planktonic cells of St. bacillaris could cause a differential expression of S. cerevisiae genes involved 240 in the fermentation process (Pourcelot et al., 2023). It should be also noted that, the different yeast 241 species could have overlapping nutritional requirements leading to competition for nutrients such as 242 amino-acids or vitamins (Evers et al. 2021). Probably, biofilm-detached cells could be more 243 competitive with S. cerevisiae and steal nutrients from it during the first steps of alcoholic 244 fermentation. This observation is in agreement with previous studies which highlighted that different 245 couples of St. bacillaris and S. cerevisiae can influence the growth dynamics, the fermentation 246 behavior and, as a consequence, wine composition in a couple-dependent manner (Englezos et al., 247 2019). On the basis of our results, the interaction between these 2 yeasts is not only couple-ependent, 248 but depends also on St. bacillaris lifestyle.

249 The lifestyle of *St. bacillaris* did not influence the main oenological parameters of Montepulciano 250 d'Abruzzo wines (Table 1). Significant differences were only observed for the content of ethanol and 251 glycerol. A slight reduction of ethanol was detected when *St. bacillaris* was inoculated as biofilm 252 detached cells. Probably, in biofilm-detached cells the acetaldehyde pathway is less active than in 253 planktonic ones. In fact, when biofilm-detached cells are inoculated a reduction of ethanol content 254 and an increase of glycerol concentration have been detected. Effectively, the low production of 255 ethanol is strictly linked to the low activity of the acetaldehyde pathway. It is already known that this 256 behaviour has large-scale effects on the metabolic fluxes, necessitating higher glycerol production to 257 compensate for reduced ethanol production and to maintain cells' redox balance (Ansell, Granath, 258 Hohmann, Thevelein, & Adler, 1997) (Fig. 2). As a direct consequence, increased production of 259 pyruvate and amino acids and larger amounts of alcohols derived from alanine, leucine, valine, and 260 isobutanol, as well as metabolites from glyceraldehyde-3-phosphate, are shown (Comitini et al., 261 2021).

262 Glycerol is the most abundant yeast metabolism by-product after ethanol and  $CO_2$ . This is a non 263 volatile 3-hydroxy alcohol and appears to contribute to the mouthfeel and sweetness of wine in the 264 range of 5–12 g/L (Ivit, Longo, & Kemp, 2020). Wines obtained with biofilm-detached cells of St. 265 bacillaris were characterized by a higher content of glycerol than those obtained with planktonic 266 cells. In particular, wines produced with biofilm-detached cells produced wines with a content of 267 glycerol ranging from 6.06 g/L (SRS1+SB8) to 9.38 g/L (SRS1+SB9), while the planktonic ones 268 ranged from 5.03 g/L (SRS1+SB7) to 8.12 g/L (SRS1+FUC17) (Table 1). Similar results have already 269 been reported when St. bacillaris was adhered to oak chips (Perpetuini et al., 2021; 2023). The 270 glycerol biosynthetic genes are up-regulated in biofilms, and the amounts of glycerol are significantly 271 higher in sessile cells compared to planktonic cells (Desai et al., 2013). In fact, the decreased glycerol 272 levels result in the down-regulation of biofilm adhesin genes such as ALS1, ALS3, and HWP1 (Desai 273 et al., 2013). It is unclear why glycerol and biofilm formation should be so closely linked. However, 274 according to Desai et al. (2013) glycerol biosynthesis is essential for proper expression of numerous 275 biofilm regulated genes, including adhesin genes. The obtained results highlighted that the number 276 of St. bacillaris viable yeast cells in the fermentation trials performed with planktonic cells was 277 characterized by a stronger cell decay (p < 0.05) than that observed in trials fermented with biofilm 278 detached ones after 7 days of fermentation. In fact, a decrease of about 2 Log CFU/mL was observed: 279 the number of St. bacillaris viable cells in fermentation trials performed with planktonic cells showed 280 a mean value of about 2.42 log CFU/mL, while that of trials inoculated with biofilm-detached cells 281 was 3.91 log CFU/mL (Fig. 3). On the contrary, the number of S. cerevisiae viable cells was similar 282 in both conditions. At the end of alcoholic fermentation, the number of biofilm-detached St. bacillaris 283 cells was about 2 Log CFU/mL, while this yeast was not detected in the trials performed with 284 planktonic cells. S. cerevisiae cells were detected in similar concentration (Fig. 3). This finding could

285 be related to the ability of biofilm-detached cells to better face the stresses of alcoholic fermentation. 286 In fact, as reported by Guilhen et al. (2016), cells dispersed from biofilms have a high stress response 287 because they are transcriptionally closer to their parent cells in biofilm form than to cells in planktonic 288 form.

289

290 *3.3* Biofilm-detached cells increase the content of pyruvic acid, anthocyanin, and polyphenols 291 Acetaldehyde is a potent volatile flavor compound that, at low levels, gives a pleasant fruity aroma, 292 but at high concentrations (higher than 100–125 mg/L), it possesses a pungent, irritating odor (Berg, 293 Filipello, Hinreiner, & Webb, 1955). Moreover, it plays a key role in the increase in color (Liu & 294 Pilone, 2000). However, it should be noted that the International Agency for Research on Cancer 295 (IARC) classified acetaldehyde as "possibly carcinogenic to humans (Group 2B)" and, in 296 combination with its oral intake via alcoholic beverages, as "carcinogenic to humans (Group 1)". 297 According to the criteria set out in Regulation (EC) No 1272/2008 (Classification, Labeling and 298 Packaging regulation), acetaldehyde is classified as carcinogenicity category 1B (may cause cancer) 299 and germ cell mutagenicity category 2 (suspected of causing genetic defects) meeting the criteria to 300 be considered a carcinogenic, mutagenic, and/or toxic for reproduction (Cartus et al., 2023). 301 Acetaldehyde content was similar in both conditions; in fact, a mean value of 40 mg/L was detected 302 in wines obtained with planktonic and biofilm-detached cells.

303 The content of pyruvic acid was higher in wines obtained with biofilm-detached cells. In particular, 304 its content ranged from 45.99 mg/L (SRS1+SB10) to 48.19 mg/L (SRS1+FUC17) and from 41.13 305 mg/L (SRS1+SB9) to 45.9 mg/L (SRS1+FUC16) in wines fermented with biofilm-detached and 306 planktonic cells, respectively (Table 2). It seems that biofilm-detached cells are more efficient at 307 redirecting sugar consumption for the production of alternative compounds, rather than ethanol, than 308 planktonic ones. These alternative compounds could be glycerol and pyruvic acid produced via 309 glycerol-pyruvic metabolisms (Fig. 2). The production of pyruvic acid has already been described in 310 *St. bacillaris* (Magyar, Nyitrai-Sárdy, Leskó, Pomázi, & Kállay, 2014; Mangani, Buscioni, Collina 311 Bocci, & Vincenzini, 2011). Generally, the production of pyruvate by wine yeasts varies from 50 312 mg/L to 120 mg/L (Morata, Gómez-Cordovés, Colomo, & Suárez, 2003). Generally, the production 313 of pyruvate, a metabolic intermediate in the biosynthesis of acetyl CoA, grows at the beginning of 314 fermentation, while its concentration decreases at the end of alcoholic fermentation. As the 315 fermentation process progresses and the availability of nutrients decreases, yeasts utilize the pyruvate 316 that was previously secreted during the earlier stages of fermentation (Morata et al., 2003). 317 The production of pyruvic acid is essential to improving wine color. In fact, according to Morata et 318 al. (2003), a linear relationship between vitisin A production and pyruvate levels can be observed. 319 Therefore, the use of biofilm-detached cells, characterized by a higher production of pyruvic acid 320 than planktonic ones, could be an interesting strategy to modulate wine color. This may be especially 321 important for red wines destined to be aged (especially if they are aged in the barrel) or are to undergo 322 a second fermentation (e.g., sparkling wines). The color of wine is also influenced by anthocyanins 323 and polyphenols, as well as the extraction, absorption and preservation phenomena of anthocyanins. 324 Therefore, their content was also evaluated. The anthocyanins were mainly absorbed by planktonic 325 cells; in fact, wines obtained with biofilm-detached cells showed levels of anthocyanins ranging from 326 506.8 mg/L (SRS1+FUC16) to 659.9 mg/L (SRS1+SB7), while those fermented with free cells of St. 327 bacillaris ranged from 518.8 mg/L (SRS1+FUC9) to 612.6 mg/L (SRS1+SB1) (Table 2). Similarly, 328 the content of polyphenols was higher in wines inoculated with biofilm-detached cells. In fact, the 329 content of polyphenols ranged from 5.7 g/L gallic acid equivalents to 6.9 g/L gallic acid equivalents, 330 and from 5 g/L gallic acid equivalents to 5.7 g/L gallic acid equivalents in biofilm-detached and 331 planktonic cells, respectively.

332 The concentration of polyphenols in wines is influenced by viticulture (grape variety and clone, light 333 exposure, degree of ripeness), yeast strains, and vinification process (destemming, crushing, pre 334 fermentation maceration, alcoholic fermentation, pressing) (Jagatic Korenika, Tomaz, Preiner, 335 Plichta, & Jeromel, 2021). For instance, according to Lisov et al. (2020) the extraction of phenolic 336 compounds during alcoholic fermentation is affected by maceration time. The best results were
337 obtained after 15 days of maceration, with exceptions of gallic acid, catechin, and myricetin.
338 Regardless of the adhesion properties of *St. bacillaris*, a negative relationship can be established
339 between the number of viable yeast and the content of anthocyanins and polyphenols, suggesting that
340 their release or adsorption is mainly dependent on the vitality of yeasts. Probably, the differences
341 observed in this study could be related to the viability of the yeast cells. In fact, cells embedded in a
342 biofilm, as well as biofilm-detached cells, are more resistant to stresses than planktonic ones.
343 According to Echeverrigaray, Scariot, Menegotto, and Delamare (2020), a negative correlation
344 between pigment adsorption and both cell viability and cell wall/membrane integrity can be observed.
345 Irrespective of their adsorptive potential during the process of wine fermentation, viable cells
346 demonstrated a limited ability to adsorb anthocyanins. Conversely, permeabilized yeast cells
347 exhibited a high capacity for pigment adsorption.

348

#### 349 3.4 Oenological parameters and wine color

350 The color of red wine is a major concern for the wine industry since it strongly affects consumer 351 demands. Anthocyanin content is the main reason for the color of red wine and depends on the grape 352 variety, degree of grape ripeness, soil, and climatic conditions. It undergoes a progressive change 353 from production to consumption of any wine due to polymerization, copigmentation, and oxidation 354 reactions. Therefore, it is important to evaluate the effect of the different oenological parameters on 355 wine color and try to predict it on the basis of these parameters.

356 Concerning the chromatic characteristics of wine, b\* values (blue/yellow color) were all low, 357 reflecting the low presence of yellow color component in Montepulciano d'Abruzzo wines (Table 3). 358 Wines obtained with biofilm-detached cells of *St. bacillaris* had lower values of b\* and h\* than those 359 obtained with planktonic cells. The lower value of h\* leads to purple or ruby red, while higher values 360 lead to brick red or reddish brown. These wines also showed higher a\* values, indicating the presence 361 of a stronger red color than the others, and lower clarity (L\*) (Table 3). No significant differences 362 were obtained for the parameter c\*, which represents the psychometric chroma. It is important to 363 underline that in 6 trials out of 10, the E values were higher than 3 CIELAB units (Table 4), indicating 364 that the color differences between wines obtained from planktonic and biofilm-detached cells could 365 be perceived by human eyes (Martinez, Melgosa, Perez, Hita, & Negueruela, 2001). These results 366 suggested that yeast's absorption of phenolic compounds could result in an increase in yellow color 367 and a reduction of blue and red nuances, indicating that not only the choice of yeast strains but also 368 their lifestyle (planktonic vs. biofilm-detached) is important to defining the color of wine. The content 369 of anthocyanins could help explain these differences. In fact, the content of anthocyanins is negatively 370 correlated with L\* values, suggesting their significant contribution to color intensity (i.e., a smaller 371 L\* value), and positively with a\*, indicating their contribution to red wine color.

372 A correlation matrix was constructed to establish the relationship between the variables considered. 373 In biofilm-detached cells, anthocyanin content was positively correlated with the concentration of 374 polyphenols, the number of cells, and a\* values. Positive relations were also present between 375 polyphenols, a\* values, and the number of cells. a\* values were positively correlated with the number 376 of cells and the content of acetaldehyde (Table 5). In planktonic cells, anthocyanins were positively 377 correlated with the concentration of polyphenols and the number of cells. Polyphenols were positively 378 related to the number of cells and a\* values and negatively to pyruvic acid. a\* values correlated 379 positively with the number of cells and negatively with the amount of pyruvic acid. As expected, the 380 content of polyphenols and anthocyanins is essential to improve red wine color in both conditions. 381 Moreover, the number of viable cells is another key factor for the determination of red wine color. In 382 fact, viable cells show a limited ability to adsorb anthocyanins on their cell wall (Echeverrigaray et 383 al., 2020).

384 A regression model was developed to predict the color of wine based on the following parameters: 385 anthocyanins, polyphenols, the number of viable yeasts, pyruvic acid, and acetaldehyde. The 386 developed model behaved fairly well for the prediction of L\*, a\*, and b\* when biofilm detached cells 387 are inoculated. In fact, r2 was 0.727, 0.878, and 0.628 for L\*, a\*, and b\*, respectively. Good regression 388 coefficients were observed also for planktonic cells: r2 values of 0.628, 0.748, and 0.623 for L\*, a\*, 389 and b\*, respectively (Fig. 4). The regression coefficient of determination of cross-validation showed 390 that the analysis of wine samples with these methods could allow predictions of wine color. It should 391 be noted that the regression model behaved better in the presence of biofilm-detached cells, 392 suggesting that their use in winemaking could be useful to predict the color of wine more accurately. 393 However, to increase the accuracy and robustness of these prediction models and to employ them in 394 commercial applications, larger sample sets can be used in future studies.

## 395

# 396 4. Conclusion

397 The results obtained in this study offer first evidence of the role of *St. bacillaris* grown as biofim 398 detached cells in the determination of Montepulciano d'Abruzzo wine color. In particular, the co 399 inoculation of biofilm-detached cells of *St. bacillaris* and *S. cerevisiae* resulted in an increase of 400 glycerol, pyruvic acid, polyphenols and anthocyanins and a decrease of ethanol content. Moreover, 401 wines obtained with biofilm-detached cells had lower values of b\* and h\* and higher a\* values, 402 indicating the presence of a stronger red color. Moreover, it should possible to predict the color of 403 young wines from must measurements. The developed model behaved fairly well for the prediction 404 of L\*, a\*, and b\* when biofilm detached cells were inoculated. This approach provides an important 405 starting point for further identification and prediction of wine quality factors from these parameters. 406 This kind of studies are of great importance to help the oenologists to better manage wine polyphenols 407 through the correct choice of yeast strain or inoculum strategy.
